

BLACK HOLES · AN ILLUSTRATED GUIDE

Where Physics Runs Out

Why our best theories break down inside a black hole, and what that really means.

> The laws of nature don't switch off at a black hole. What fails is our *description* of them. At the centre, Einstein's general relativity predicts infinities it cannot make sense of, and quantum mechanics has never been joined up with it. This guide explains why, step by step and in plain language.

Spacetime · Singularities · Hawking radiation · Information

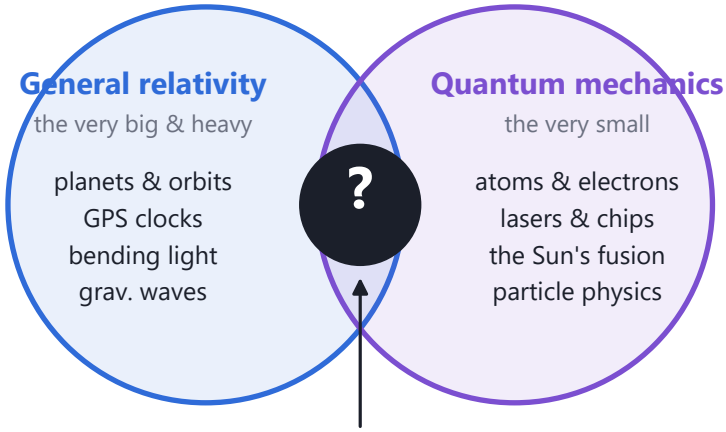

November 2026

BEFORE WE START

The short answer

~~"The laws of physics break down in a black hole."~~

Better: **our current theories stop giving sensible answers at the centre of a black hole.**

Physics runs on two hugely successful theories that have never been unified. General relativity handles heavy things; quantum mechanics handles tiny things. A black hole's centre is both at once.

Where does it actually fail?

Not at the event horizon. The horizon is the famous point of no return, but the equations there are perfectly well behaved. A falling astronaut wouldn't notice anything special when crossing it.

At the singularity. There, general relativity predicts infinite curvature, and paths through spacetime simply end. An infinity in an equation usually means the theory has gone beyond the range where it works.

01 · THE FOUNDATION

Gravity is the shape of spacetime

Einstein replaced Newton's invisible pulling force with something stranger: mass bends space and time, and everything moves along the bends.

The classic picture. A heavy mass curves the “fabric” around it, and a planet (orange) rolls around the dip in an orbit. The real curvature is in four-dimensional spacetime, including time, so treat this as an analogy, not a literal sheet.

The central idea

In general relativity, matter and energy tell spacetime how to curve, and curved spacetime tells matter and light how to move. A planet orbiting a star isn't being tugged on a string. It is moving as straight as it can through curved spacetime. Such a “straightest possible path” is called a **geodesic**.

Near a black hole that curvature becomes extremely strong. That's where the theory gets pushed hardest, and eventually past its limits.

$$G_{\mu\nu} + \Lambda g_{\mu\nu} = (8\pi G / c^4)\, T_{\mu\nu}$$

Left side: the geometry of spacetime (how it curves).
Right side: the matter and energy present.
It reads: **“stuff here ⇄ curvature here.”** It's a relationship, not a claim that space literally tears like cloth.

IN SIMPLE TERMS

Imagine ants walking “straight ahead” on a curved apple. Their paths bend together even though no force pushes them. That bending is what we feel as gravity.

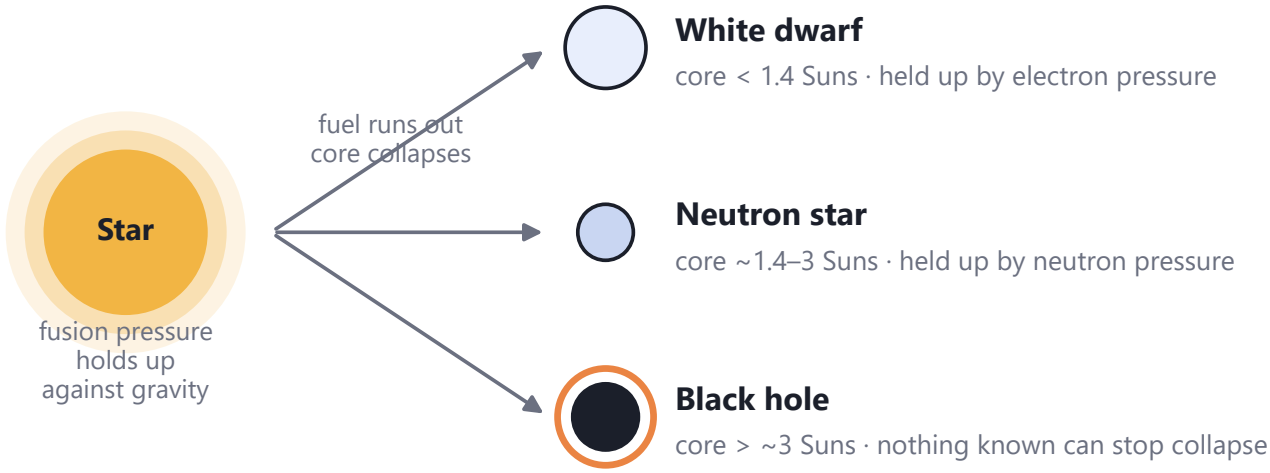

HOW SURE ARE WE?

Very. Bending of starlight (gravitational lensing), gravitational waves, precise orbits and images of the regions around black holes all match general relativity, even in strong gravity. But none of these tests reach the singularity itself.

02 · COLLAPSE

How black holes are born

A black hole doesn't form just because a star is big. It forms when nothing is left that can hold back gravity.

Three possible endings for a star's core. Above about three solar masses, no pressure we know of can halt the collapse.

A tug-of-war that gravity wins

For most of a star's life, heat and pressure from nuclear fusion push outward and balance gravity's inward pull. When the fuel runs low, the core contracts. Depending on its mass it becomes a white dwarf, a neutron star, or it keeps collapsing.

Past a certain point the collapse creates a **trapped region**: a zone where even light aimed outward is forced inward.

The first model (1939)

Oppenheimer and Snyder calculated the collapse of an idealised, perfectly round cloud of pressureless dust. It's not a realistic star, but it showed that collapse really can produce a black hole. Today, supercomputer simulations (numerical relativity) handle real stars with pressure, spin and magnetic fields.

Trapped surfaces

Picture a flash of light going off on the surface of a sphere. Normally the outward-going part of the flash spreads out and the inward part shrinks. On a **trapped surface**, *both* parts shrink. Even the "outward" light is losing ground.

IN SIMPLE TERMS

"Escape velocity faster than light" is a handy slogan, but the real reason is geometric. Space is shaped so that every direction you could travel leads further in.

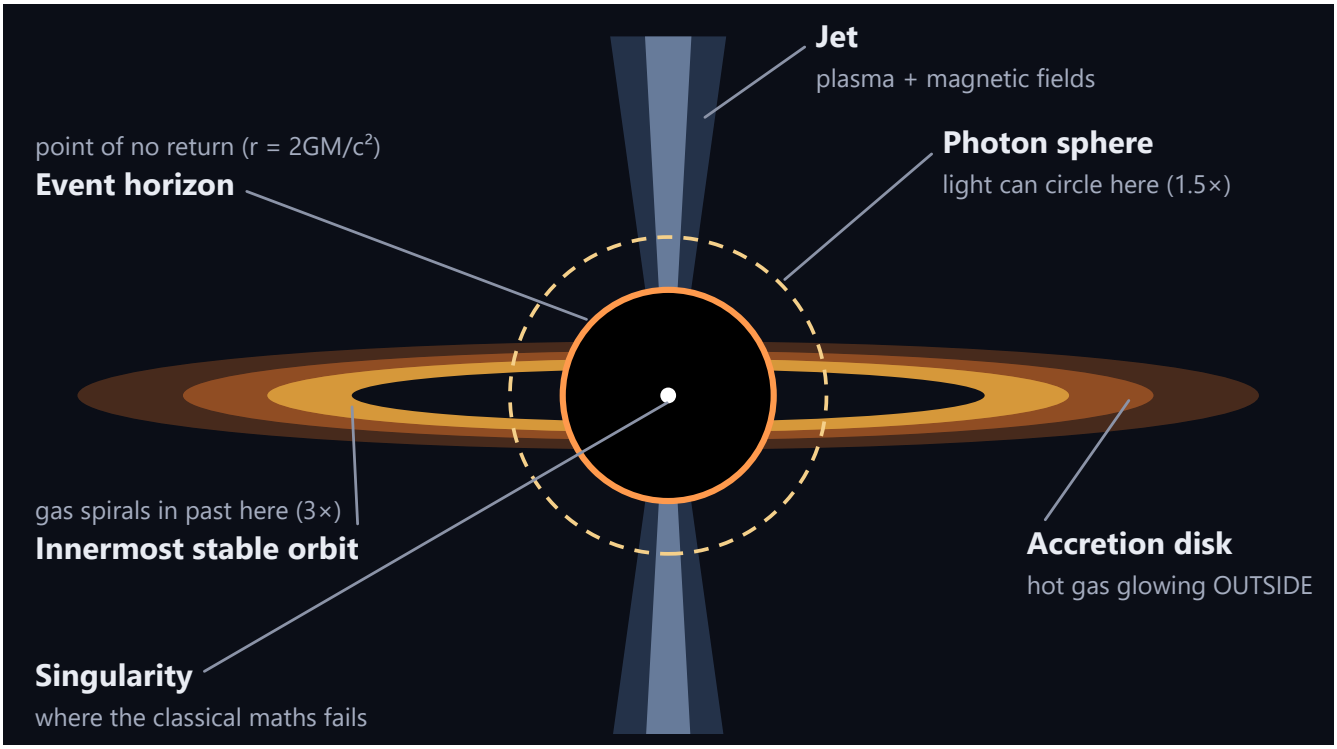

Penrose's theorem

Roger Penrose proved that once a trapped surface forms (and matter behaves normally), some paths through spacetime *must* come to an end. So the singularity is not an accident of assuming perfect roundness. But the theorem says the classical theory reaches a limit. It doesn't describe what is physically there.

03 · STRUCTURE

Anatomy of a black hole

A black hole has more structure than the dark circle in a picture. Almost everything we can see happens outside the horizon.

Schematic, not to scale. Distances in brackets are multiples of the horizon radius for a non-spinning black hole.

Event horizon: the boundary beyond which no signal can ever reach the outside universe. It is not a solid surface.

Photon sphere: where gravity is strong enough to bend light into a circle. Light here is balanced on a knife-edge.

Accretion disk: gas spiralling inward, heated to millions of degrees by friction. It glows brightly, and all of that glow comes from *outside* the horizon.

Jets: beams of plasma launched by magnetic fields and spin. They are not material escaping from inside.

$$r_s = 2GM / c^2$$

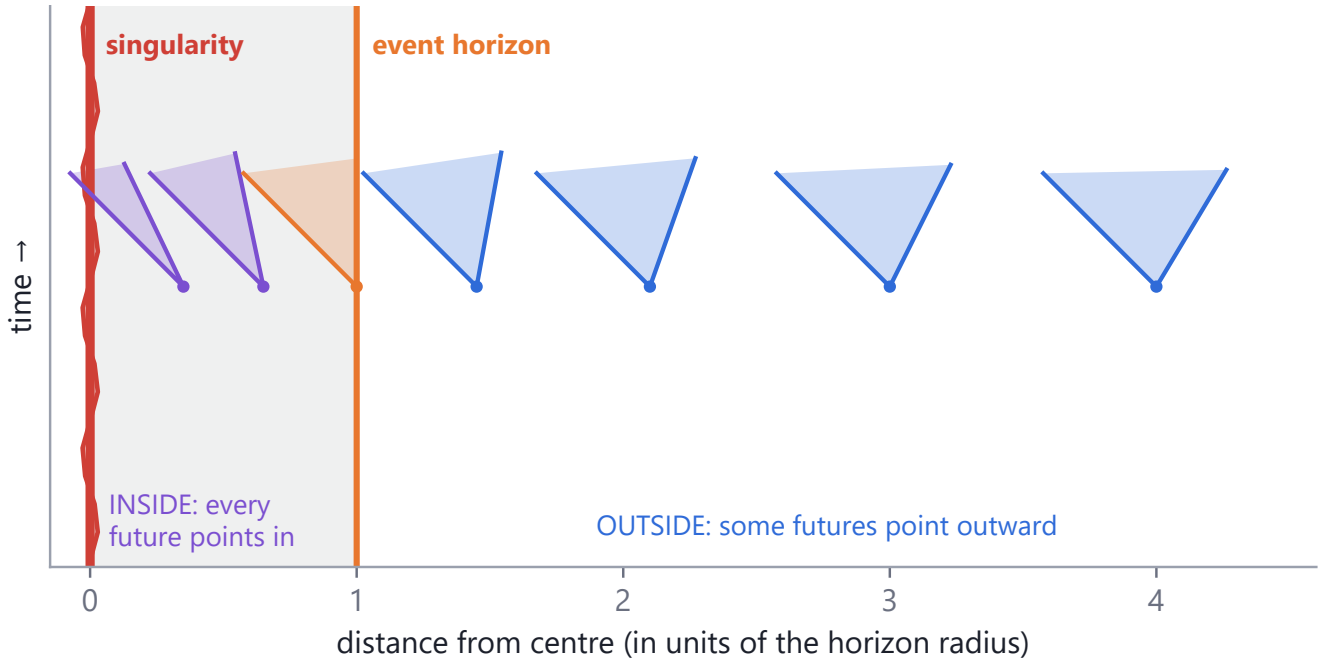

The **Schwarzschild radius**, the horizon size of an ideal, non-spinning black hole. Double the mass and the horizon doubles: about **2.95 km per solar mass**.

IF THIS WERE SQUEEZED…	HORIZON RADIUS
Earth	≈ 9 mm (a marble)
The Sun	≈ 3 km
A 10-Sun stellar black hole	≈ 30 km
Sagittarius A* (our galaxy's)	≈ 12 million km
M87* (giant)	≈ 130 × Earth–Sun

04 · CAUSALITY

Why nothing escapes: tipping light cones

Light always moves at the same local speed. A black hole doesn't slow it down. It reshapes which directions count as “the future.”

Each cone shows where light could go next from that spot (time runs upward). Outside (blue), one edge of every cone still points outward, so light can escape. At the horizon (orange) the outward edge points straight up, so light there just hovers. Inside (purple) the whole cone tips toward the centre. Drawn from the exact Eddington–Finkelstein geometry.

What a light cone is

From any event, imagine a flash of light. Its spread through space and time makes a cone, and anything with mass must travel *inside* it. Your possible futures live in that cone.

Gravity tilts the cones. Near a black hole they lean inward more and more. At the horizon, the outward edge of the cone lines up exactly with the horizon. Inside, every future direction points to smaller radius.

Why a bigger rocket doesn't help

In Newton's picture, escape is just about speed. In relativity, inside the horizon there is **no path into your future that leads outward**. A rocket of unlimited power still has to stay inside its own light cone, and the whole cone points inward.

HELPFUL ANALOGY (WITH A WARNING)

Imagine space flowing inward like a river, faster than light can swim against it. It helps the intuition, but space isn't literally a fluid. The precise statement is about light cones.

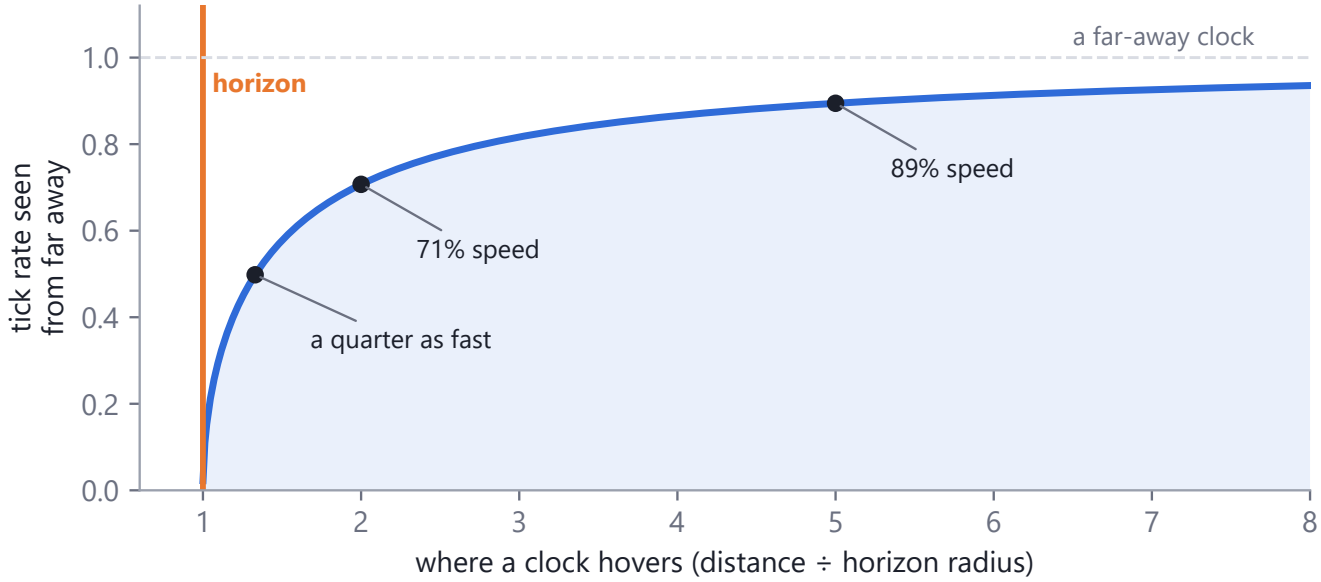

KEY POINT

The horizon is a causal boundary, not a physical wall that light hits. Locating it exactly requires knowing the entire future of the spacetime.

05 · TIME

The horizon is not a magic wall

Crossing the event horizon of a large black hole is not dramatic for the person falling in. The drama is in what outside observers see.

Gravitational time dilation. A clock hovering close to the horizon ticks slowly compared with a far-away clock, and its light reaches us stretched to redder colours. Holding still that close needs enormous rocket thrust. Nobody can hover exactly on the horizon.

Three different “times”

Most black-hole myths come from mixing these up:

- **Proper time**: what your own wristwatch shows.
- **Coordinate time**: a label from a chosen mathematical map.
- **Signal time**: when far-away observers *receive* your light.

Your watch reaches the horizon in a finite time. Distant observers see your signals arrive more and more delayed and redshifted, so you seem to freeze and fade. Both are true. They describe different things.

Gravitational redshift

Light climbing out of a gravity well arrives with less energy, shifted toward red. That isn't “tired light.” It's how clocks at different heights compare in curved spacetime. The factor involved is $(1 - r_s/r)$, which heads to zero at the horizon.

MYTH CHECK

“A falling person sees the whole future of the universe.” No. You can only see light that actually reaches you. Extreme time dilation for *hovering* observers doesn't give a *falling* one a fast-forward view of cosmic history.

06 · INSIDE THE HORIZON

Inside, the centre is in your future

"Space and time swap places" is a popular shortcut. The real point is deeper: inside, the singularity is not a place you could steer around. It's a moment you can't avoid.

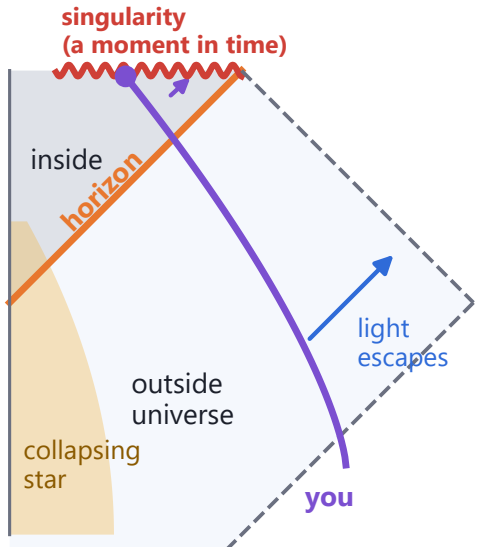

Why inward becomes unavoidable

In the usual Schwarzschild coordinates, the labels for "radius" and "time" change character at the horizon. But coordinates are just labels, and other maps are perfectly smooth there. The statement that holds in every coordinate system is about causes and effects: **inside, no future path returns to the outside**.

In the ideal, non-spinning black hole, the singularity lies *ahead in time* for anyone inside. Moving toward it is less like being pulled toward a distant object and more like being unable to stop tomorrow from arriving.

Reading the diagram

The diagram on the right is a **Penrose diagram**: the whole infinite spacetime squeezed onto one page, with light always moving at 45°. A star collapses (yellow), a horizon forms (orange), and anyone who crosses it (purple) is carried to the singularity, drawn as a jagged line across the top. It is a *time*, not a point in space.

Penrose diagram of a black hole formed by collapse. Light travels along diagonal lines.

IN SIMPLE TERMS

Outside, you can choose to go left, right, in or out, but you can't choose to stop moving forward in time. Inside the horizon, "inward" becomes just as unavoidable as "forward in time."

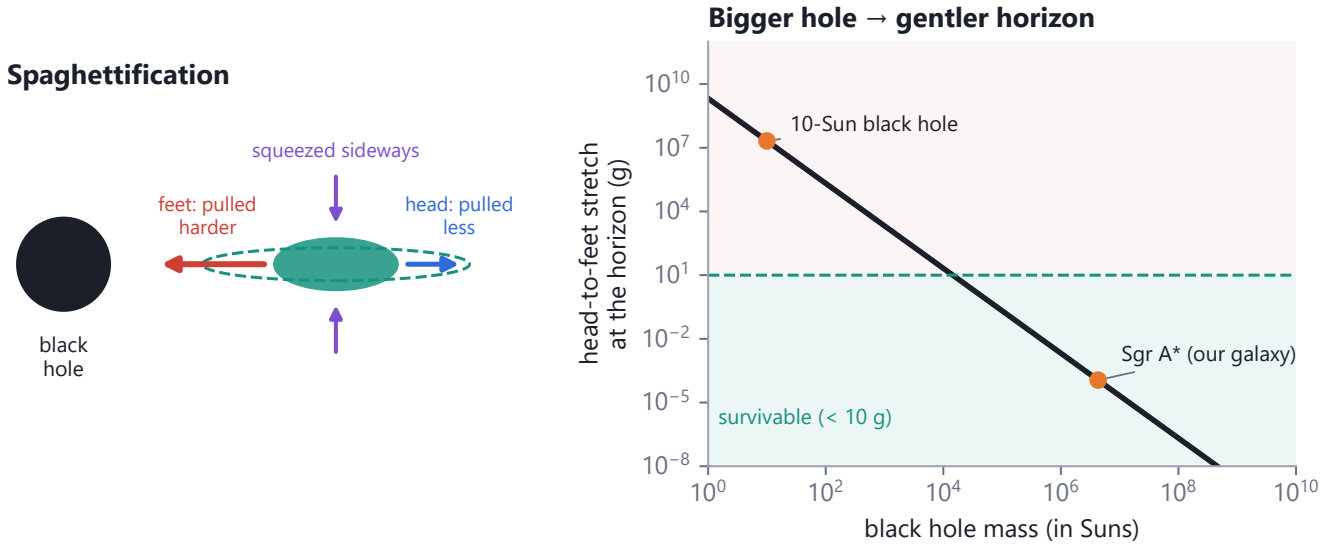

IMPORTANT LIMITATION

Real black holes spin (see page 10). The spinning, or Kerr, solution has a far stranger interior, with an inner horizon that appears to be unstable. Nobody has observed any black hole's interior, so it's misleading to say every black hole contains a simple point at the centre.

07 · TIDAL FORCES

Tides and spaghettification

What hurts isn't gravity's strength. It's the *difference* in pull from one end of your body to the other.

Left: feet nearer the hole are pulled harder than the head, so the body is stretched lengthwise and squeezed sideways. Right: the stretch felt at the horizon for a 2-metre person, from the Newtonian estimate below. The bigger the black hole, the gentler its horizon.

How tides stretch

The same effect raises ocean tides on Earth: the Moon pulls the near side of Earth slightly harder than the far side. Near a compact mass the difference becomes enormous. You get stretched radially and compressed from the sides. Physicists really do call this **spaghettification**.

$$\Delta a \approx 2GML / r^3$$

The difference in pull across a body of length L at distance r. Because of the r^3, getting closer makes it rapidly worse.

A surprising size effect

The horizon radius grows in step with the mass. So at the horizon, tidal stretching actually *falls* as the black hole gets heavier, by the square of the mass.

BLACK HOLE	STRETCH AT HORIZON
10 Suns	≈ 20 million g: lethal well before
Sgr A*, 4 million Suns	≈ 0.0001 g: unnoticeable

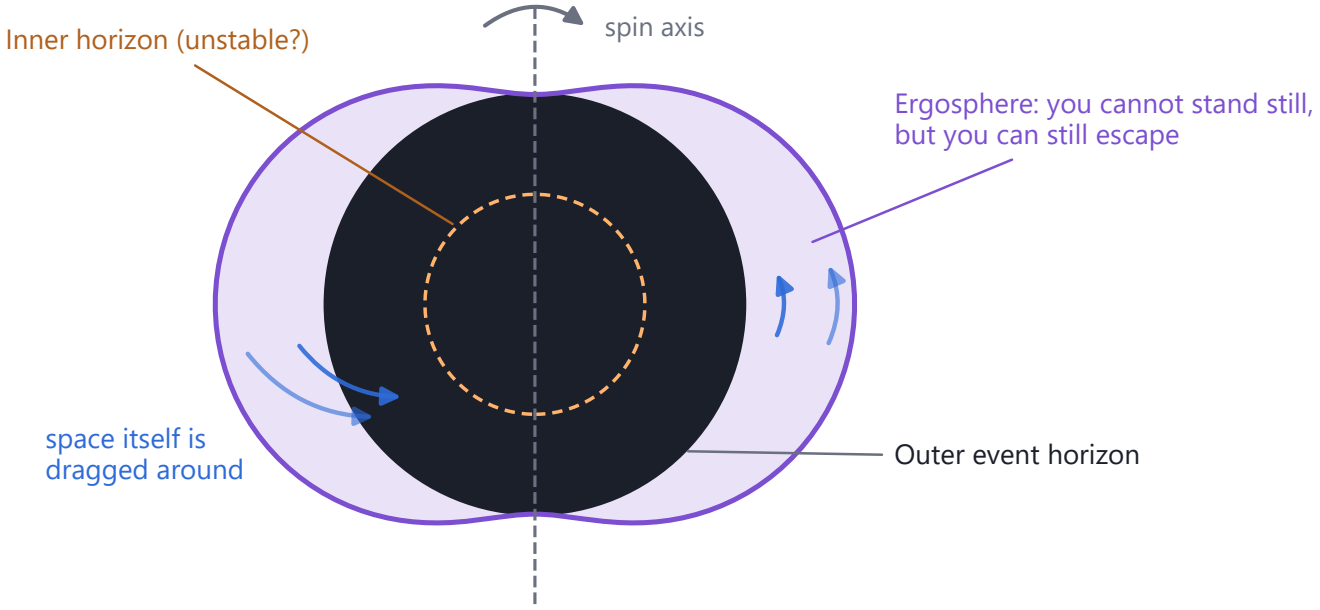

BUT…

You could in principle cross a supermassive horizon unharmed. Further in, the classical theory says tides grow without limit, so the deep interior is lethal no matter what.

08 · ROTATION

Real black holes spin

Stars rotate, so the black holes they leave behind should too. Spin changes the geometry dramatically.

Cross-section of a rapidly spinning (Kerr) black hole. The purple pumpkin shape is the ergosphere, which bulges at the equator. Inside the outer horizon lies an inner horizon.

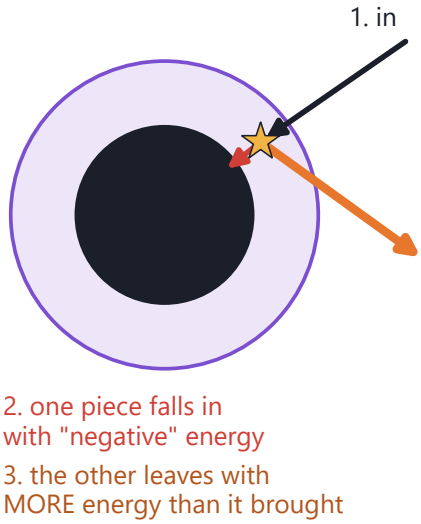

Frame dragging and the ergosphere

Roy Kerr found the exact solution for a spinning black hole in 1963. Its spin twists spacetime around it, an effect called **frame dragging**. Spin is measured by a = J/(Mc), where J is angular momentum. In natural units its size can't exceed one.

Just outside the horizon lies the **ergosphere**. Space there is dragged so hard that nothing can stay still relative to the distant stars; you're forced to swirl with it. You can still escape, though.

Stealing energy: the Penrose process

A particle enters the ergosphere and splits. One piece falls in with “negative” energy (as counted from far away). The other leaves with *more* energy than the original. The extra comes from the black hole's spin. Real jets are powered mainly by magnetic fields tapping spin energy, not literal particle splitting.

The Penrose process, in which spin energy is extracted inside the ergosphere.

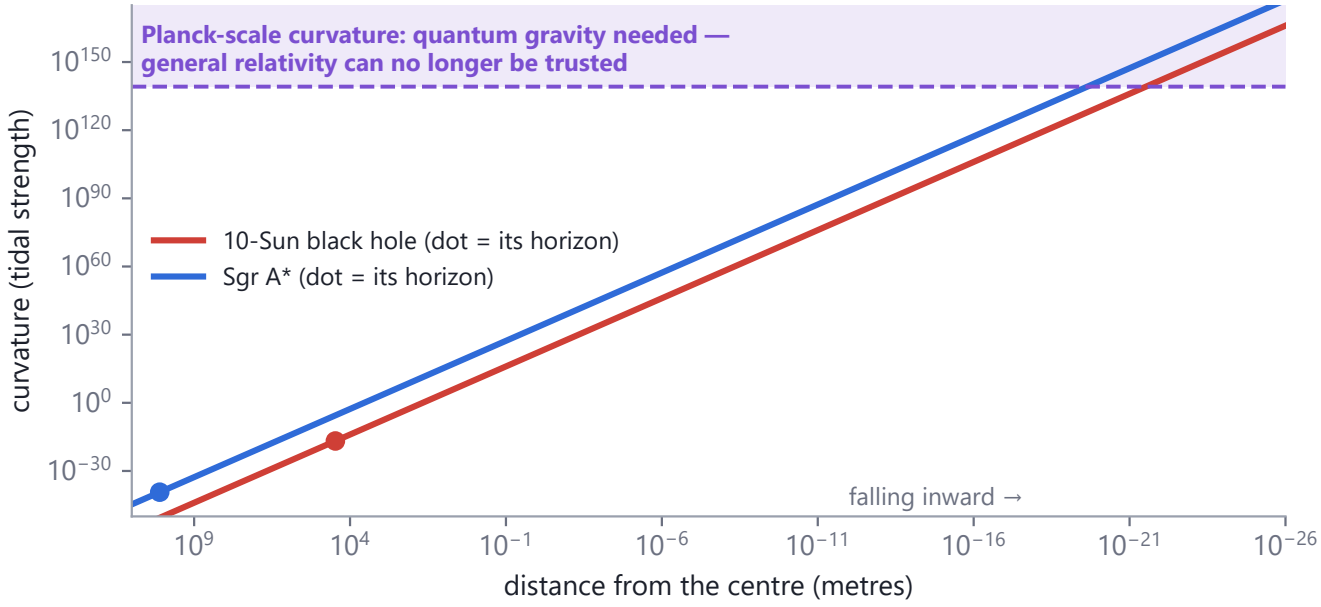

THE INNER HORIZON PROBLEM: ANOTHER PLACE THE MATHS STRUGGLES

The exact Kerr solution has an inner horizon. Ripples falling in pile up there and get blueshifted to enormous energies (“mass inflation”). This suggests the neat idealised interior wouldn't survive in a real, disturbed black hole. What actually happens is an open research question.

09 · THE BREAKING POINT

What is a singularity?

An infinity in an equation is not automatically a real physical object. It's usually a sign that the theory is being used outside its range.

Curvature (tidal strength) as you fall toward the centre, for a stellar black hole and for Sgr A*. Both curves shoot upward without limit. Long before reaching zero, they cross into the purple zone where quantum effects of gravity must matter and general relativity's predictions can't be trusted.

A real infinity vs a fake one

Some infinities come from a bad choice of map. Schwarzschild's original coordinates misbehave at the horizon, but switch to better coordinates and the problem disappears. The centre is different. Curvature measured in a way that every observer agrees on keeps growing:

$$K = 48\,G^2M^2 \,/\, (c^4\,r^6)$$

The **Kretschmann scalar**, a coordinate-free measure of curvature. As $r \to 0$, $K \to \infty$. No change of coordinates removes this.

Paths that just stop

The singularity theorems of Penrose and Hawking show something more general: under broad conditions, some paths through spacetime **can't be continued**. A falling clock would simply have no "next tick" in the theory. This is called *geodesic incompleteness*.

It does *not* prove there's a literal point of infinite density. It proves the classical description runs out.

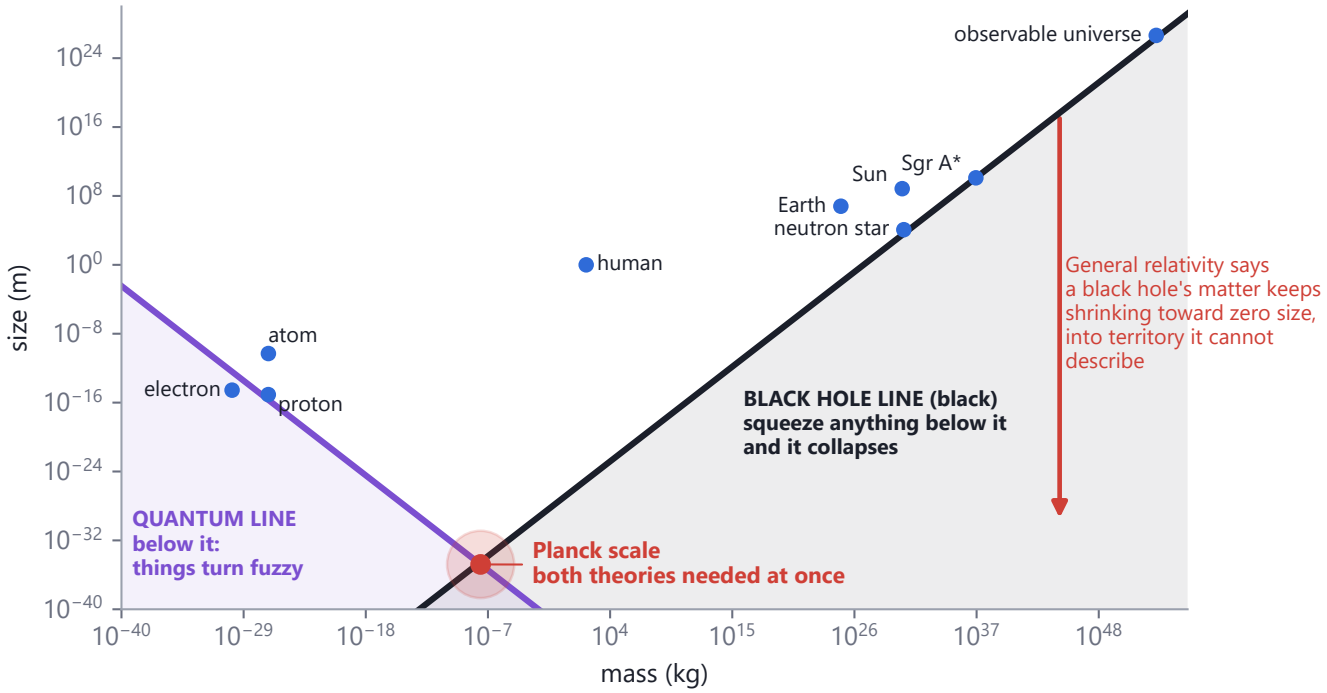

THIS IS THE REAL BREAKDOWN

Quantum effects might change the interior before any infinity arises. No experimentally confirmed theory yet tells us what replaces the classical singularity.

10 · THE MISSING INGREDIENT

Why general relativity reaches its limit

General relativity treats spacetime as perfectly smooth. Everything else in nature is quantum, so somewhere that smoothness has to give.

Everything in the universe plotted by mass and size. The black line marks the black-hole limit; the purple line marks where quantum fuzziness takes over. They cross at the Planck scale (red), where neither theory works alone. A black hole's collapsing matter is driven down toward exactly that corner.

Smooth geometry meets a quantum world

Atoms and particles obey quantum mechanics: they're fuzzy, uncertain and come in lumps. But spacetime in general relativity is classical: smooth and exact. At extreme curvature, the geometry itself should start to jitter quantum-mechanically, and treating it as smooth stops being a good approximation.

$$\ell_P = \sqrt{(\hbar G / c^3)} \approx 1.6 \times 10^{-35}\ \text{m}$$

The **Planck length** combines quantum theory (ħ), gravity (G) and relativity (c). It's where quantum gravity is expected to matter. It is not a proven "smallest possible length."

Why a new theory is so hard

Quantum theories normally describe particles moving on a fixed stage of spacetime. In general relativity, the stage itself moves and bends. A complete theory has to describe **quantum states of the stage**, keep cause and effect working, and make predictions we can test.

IN SIMPLE TERMS

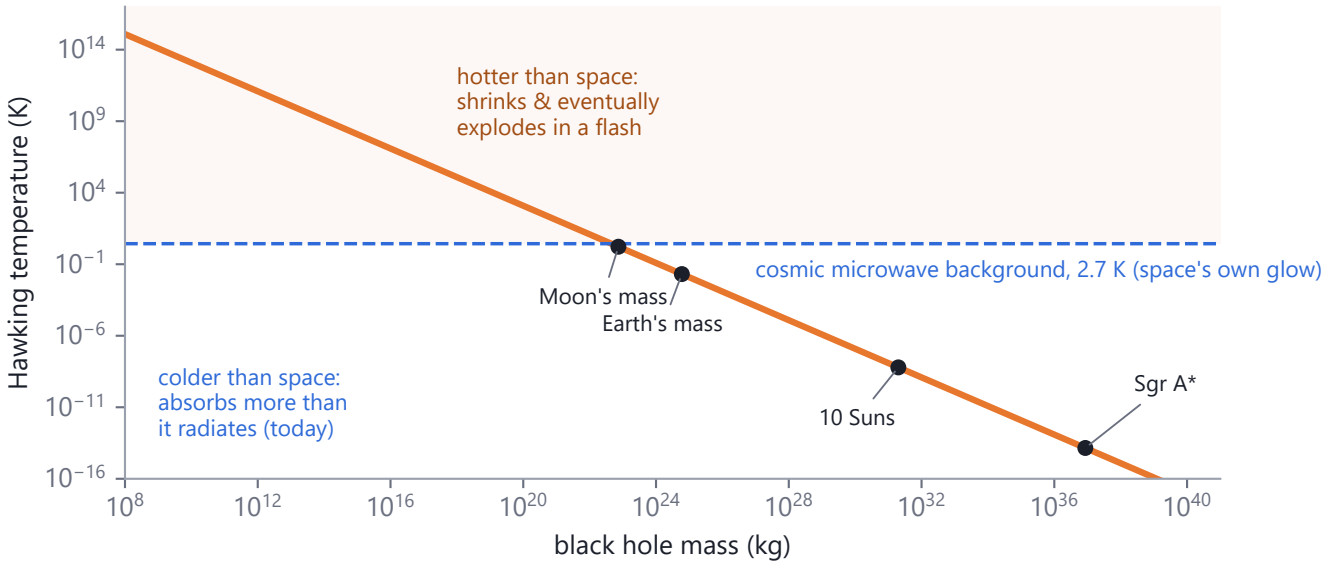

General relativity is like a superb map of the land. Zoom in far enough and you find the map is made of pixels it never knew about. The singularity is where we've zoomed in too far.

At ordinary energies, gravity *can* be treated quantum-mechanically as an approximation (an effective field theory). It's only at Planck-scale energies, like a black hole's centre, that we have no reliable answer.

11 · QUANTUM FIELDS NEAR A HORIZON

Black holes aren't completely black

In 1974 Stephen Hawking added quantum fields to a curved spacetime and found that black holes should glow, very faintly.

Hawking temperature versus mass. Heavier means colder. Every black hole we know of is far colder than the 2.7 K microwave glow that fills space, so today it absorbs more than it emits. Only a hole lighter than about the Moon would be hotter than space.

The result

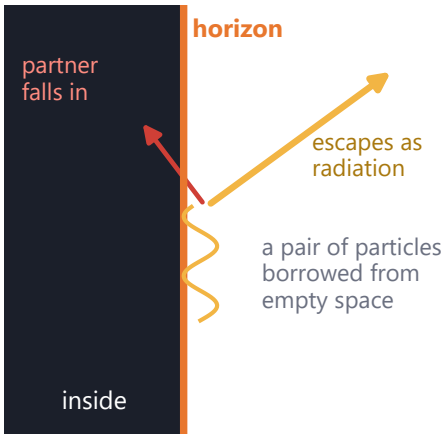

Hawking's semiclassical calculation (quantum fields on a classical curved background) predicts that a black hole emits radiation with a nearly thermal spectrum, as if it had a temperature:

$$T_H = \hbar c^3 / (8\pi G M k_B)$$

Mass M sits on the bottom, so bigger black holes are colder. A Sun-mass black hole: about 0.00000006 K.

Why it matters

Radiation carries energy away, so an isolated black hole slowly loses mass and could eventually evaporate. That's a staggeringly long time: about 10^{67} years for a Sun-mass hole. This is where gravity, quantum theory and heat first meet in one formula.

Cartoon only. The popular picture shows a particle pair split at the horizon. The real result is a global property of quantum fields and the horizon's causal structure, not particles being torn apart at a point.

NOT YET OBSERVED

For real black holes the signal is far too faint and is swamped by the cosmic background. Lab "analogue black holes" in fluids and optics mimic the maths of horizons, but they aren't detections of real evaporation.

12 · THERMODYNAMICS

Black holes have entropy

If something has a temperature, it should also have entropy, a count of its hidden internal arrangements. For black holes, that count turns out to be very strange.

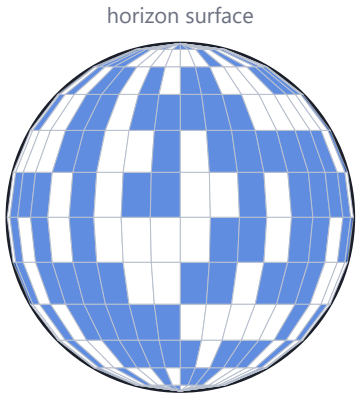

Entropy measured by area

Jacob Bekenstein proposed that a black hole's entropy is proportional to its horizon **area**. Hawking's calculation then fixed the exact number:

$$S = k_B\, c^3\, A \,/\, (4G\hbar) = k_B\, A \,/\, (4\ell_P{}^2)$$

Entropy = horizon area counted in tiny Planck-sized tiles, divided by four.

For a normal gas, entropy grows with *volume*: double the box, double the room for disorder. Here it grows with *surface area*. That hints that gravity's deepest degrees of freedom are organised in a fundamentally different way, which led to the idea of **holography**.

A picture of the area law. The horizon behaves as if it were tiled with bits of information.

The four laws: a perfect mirror

LAW	ORDINARY THERMODYNAMICS	BLACK-HOLE MECHANICS
0th	Temperature is uniform in equilibrium	Surface gravity is uniform on the horizon
1st	Energy is conserved: dE = T dS + …	dM = (surface gravity / 8π) dA + spin and charge terms
2nd	Entropy never decreases	Horizon area never decreases (classically)
3rd	You can't reach absolute zero	You can't reduce surface gravity to zero

THE GENERALIZED SECOND LAW

Hawking radiation *shrinks* the horizon, which breaks the area rule. The fix is to add up everything: $S_{total} = S_{black\ hole} + S_{outside}$. That total never decreases, a deep bridge between gravity, quantum fields and heat.

WHY IT MATTERS

Entropy means there are hidden microscopic states. Any quantum gravity theory must be able to count them. String theory has done this exactly for certain special black holes, a major success.

13 · THE PARADOX

The information paradox

Combine Hawking radiation with the rules of quantum mechanics and two of physics' most trusted principles collide head-on.

The puzzle in three steps. Quantum mechanics says the book's information can be scrambled but never truly deleted. Hawking's original calculation says the final radiation carries no trace of it.

Quantum rule: information survives

Quantum evolution is **unitary**: given the complete final state, you could in principle run time backwards and recover the starting state. Burn a book and the information is hopelessly scrambled in smoke, ash and heat, but not destroyed.

Gravity's answer: it's gone?

A black hole is described from outside by just mass, spin and charge (the "no-hair" idea). If it then evaporates into perfectly *thermal* radiation, which is random and featureless, nothing seems to record what fell in. A pure, fully specified quantum state would have turned into a mixed, random one. Quantum mechanics forbids that.

Why it's a big deal

Something has to give:

- Information is truly lost, and quantum mechanics is wrong in gravity.
- The information escapes in subtle correlations in the radiation.
- Something survives, such as a tiny remnant.
- Our picture of the horizon or interior is wrong.

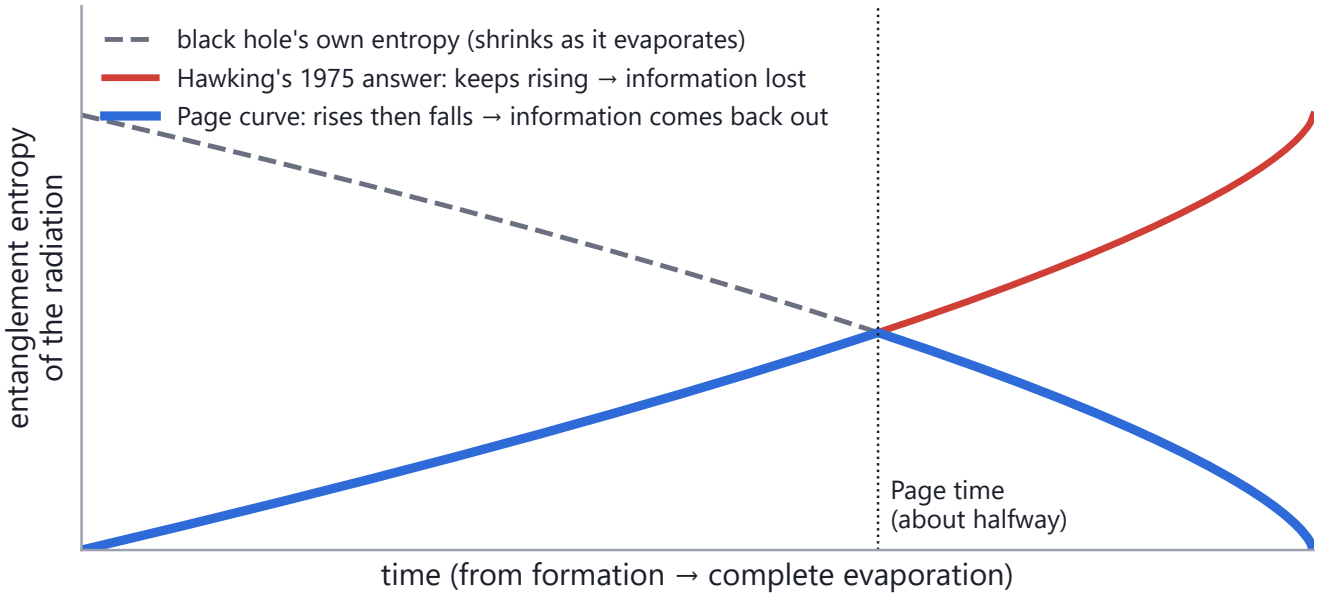

BE PRECISE

The paradox is a clash between theoretical principles. Nobody has observed information vanishing. It's a thought experiment that shows our theories don't fit together, which is exactly what this guide is about.

14 · MODERN PROGRESS

The Page curve and “islands”

Since 2019, new calculations have reshaped the information debate and point toward information coming back out.

Entanglement entropy measures how much the radiation is “entangled” with what's left behind. If information is preserved, it must rise and then fall back to zero: the Page curve (blue). Hawking's original answer (red) keeps rising forever.

What a “no loss” answer looks like

Early on, each bit of radiation is entangled with the black hole, so the radiation's entropy climbs. If nothing is lost, then after roughly half the hole has evaporated (the **Page time**), later radiation must start revealing the hidden correlations. The entropy falls back to zero when the hole is gone. Don Page worked this out in 1993.

IN SIMPLE TERMS

Think of a secret message read out one word at a time, scrambled. The early words look like nonsense. Only after you've heard more than half do the pieces start to fit together.

Islands and replica wormholes

New semiclassical calculations use *quantum extremal surfaces* and *replica wormholes*. When computing the radiation's entropy, they include a region behind the horizon called an **island**. With the island counted, the maths reproduces the Page curve.

WHAT REMAINS UNRESOLVED

This is real progress, but it's done in simplified model universes. Physicists still debate what the interior really is, how spacetime itself emerges, and exactly how information gets out. Getting the entropy right is not the same as a complete, tested account of everything inside a black hole.

15 · LOOKING FOR THE NEXT THEORY

What might replace the singularity?

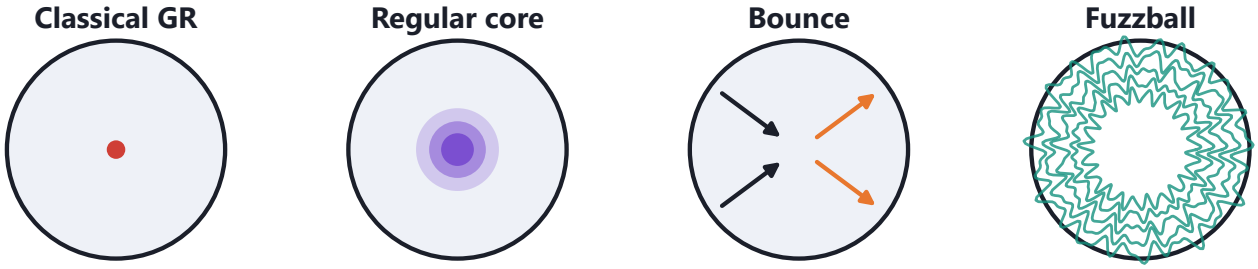

Several research programmes are trying to build the theory that takes over where general relativity runs out.

String theory & holography
Replaces point particles with tiny vibrating strings, which naturally include gravity. Holography links a gravitational universe to a quantum theory on its boundary, without gravity, especially in "anti-de Sitter" model universes.

Loop quantum gravity
Quantizes geometry itself, so that area and volume come in discrete chunks. Some models replace the singularity with a "bounce."

Asymptotic safety
Asks whether gravity, viewed at ever-higher energies, settles into a well-behaved "fixed point" instead of blowing up.

Causal dynamical triangulations
Builds spacetime from tiny building blocks glued together with cause and effect built in, then lets the shape emerge.

Some proposed pictures of what lies at the centre. Only the first is a prediction of an established theory, and it's the one we know can't be the full story.

SPECULATIVE IDEAS

Regular cores, bounces, remnants, fuzzballs and white holes all appear in models. Wormholes appear in mathematical solutions, but there's **no evidence that an ordinary black hole is a traversable portal**.

HOW TO JUDGE A PROPOSAL

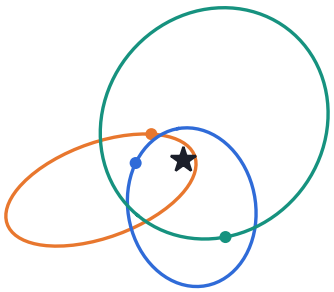

A winning theory must (1) reproduce general relativity and quantum physics where they already work, (2) resolve the contradictions, and (3) make testable predictions. Elegance alone isn't confirmation.

16 · EVIDENCE

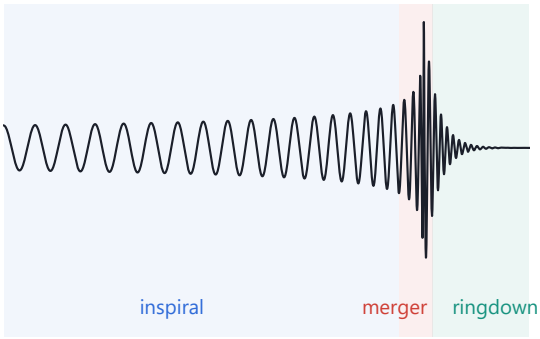

Testing gravity without seeing inside

We can't look past the horizon, but we can test gravity right up to its edge.

1. Stars orbiting Sgr A*

2. Gravitational-wave "chirp"

3. Event Horizon Telescope

Three windows on black holes: stellar orbits, gravitational waves and horizon-scale radio images (illustrative sketches).

1 · Stars racing around Sgr A*

Decades of tracking stars at the Milky Way's centre reveal a compact object of about 4 million solar masses packed into a tiny volume.

2 · Gravitational waves

Orbiting black holes ripple spacetime and spiral together. LIGO first detected this in 2015. The signal has three phases: **inspiral** (a rising “chirp”), **merger** (the horizons join, modelled with supercomputers) and **ringdown** (the new hole “rings” like a bell as it settles). The ringing tones depend only on mass and spin, which makes them a precise test of the Kerr prediction. This is called black-hole spectroscopy.

3 · The Event Horizon Telescope

Radio dishes across the globe link up into an Earth-sized telescope. It imaged M87* in 2019 and Sgr A* in 2022. The dark centre is a **shadow** made by light being captured and bent. The bright ring is hot gas whose light has been lensed around the hole. It is not a photo of the horizon.

AVOID OVERCLAIMING

None of this shows the singularity or the interior. A wave signal doesn't prove an infinite-density point exists. Any deviation found later might come from messy gas and magnetic fields rather than new physics, so strong claims need several independent observations.

17 · PUTTING IT TOGETHER

Myths, facts and the big takeaway

The weirdest claims about black holes are often where precision matters most.

MYTH **Gravity becomes infinitely strong at the horizon.** FACT Tides at a big black hole's horizon can be gentle. The horizon is a causal boundary, not where curvature blows up.

MYTH **Black holes suck everything in like a vacuum cleaner.** FACT From far away, a black hole pulls just like any other object of the same mass. If the Sun became a black hole, Earth would keep the same orbit.

MYTH **Light slows down and gets stuck.** FACT Light always moves at c locally. The light cones tip so that every future direction points inward.

MYTH **A falling person watches the whole future of the universe.** FACT You only see light that reaches you along your path. There's no cosmic fast-forward.

MYTH **The EHT photographed the event horizon.** FACT It imaged the shadow and glowing gas around the horizon, bent by gravity.

MYTH **Black holes destroy the laws of physics.** FACT General relativity predicts situations where it becomes incomplete. That shows our theory is unfinished, not that reality stops following rules.

Black holes as engines

Black holes aren't only dead ends. Gas spiralling into supermassive ones powers quasars, among the brightest objects in the universe, and launches jets that heat gas and shape how whole galaxies form stars. All of that energy comes from matter *outside* the horizon.

THE CENTRAL TAKEAWAY

Black holes are laboratories for the limits of our knowledge. The horizon is well understood in classical geometry. The singularity and the information puzzle show exactly where the next theory is needed: one that unites the smooth spacetime of Einstein with the quantum world.

REFERENCE

Glossary and sources

Glossary

Event horizon: the boundary of no escape; a causal limit, not a surface.

Geodesic: the straightest possible path through curved spacetime.

Proper time: the time measured by a clock carried along a path.

Light cone: all the directions light can travel from an event; it bounds your possible futures.

Trapped surface: a closed surface where even outward-going light converges.

Singularity: where classical spacetime cannot be extended; paths end and curvature diverges.

Ergosphere: the region around a spinning hole where nothing can stand still.

Entropy: a measure of hidden microscopic arrangements, or missing information.

Unitarity: the quantum rule that information and total probability are preserved over time.

Page time: the moment, about halfway through evaporation, when radiation entropy should peak.

Quasinormal modes: the "ringing tones" of a disturbed black hole settling down.

Quantum gravity: the hoped-for quantum theory of gravity and spacetime.

A NOTE ON CERTAINTY

Statements about the interior and about quantum-gravity proposals are marked here as theoretical or unresolved, not established observation. Diagrams are schematic unless noted.

FINAL THOUGHT

The most intriguing thing about a black hole is not that it defies every rule. It's that our best-tested rules point to a frontier where a deeper explanation must exist.
